Mistakes in refractory coeliac disease and how to avoid them

Umberto Volta, Giacomo Caio and Roberto De Giorgio

Refractory coeliac disease (RCD) is characterized by the persistence or recurrence of symptoms and signs of malabsorption associated with villous atrophy in patients with coeliac disease who have adhered to a strict gluten-free diet (GFD) for more than 12 months.\(^1\) Serology is usually negative or, in a small percentage of cases, positive at a low titre.\(^4\) Splenic hypofunction, a risk factor for RCD, can be indicated by Howell–Jolly bodies and pitted red cells in a peripheral blood smear. A reduced spleen size visible on ultrasound examination also provides direct evidence of hyposplenism.\(^5\)

RCD is subdivided into two main clinical subsets—primary and secondary. Patients with primary RCD show no improvement on a GFD, whereas those with secondary RCD experience symptom relapse after a variable period of wellbeing.\(^1\)–\(^3\) RCD can be also classified as type 1 and type 2 (table 1). RCD type 1 and 2 have a similar incidence (0.04% to 1.5%) and age at diagnosis (generally after the age of 50 years);\(^6\) however, they differ significantly in terms of complications, prognosis and treatment options, making correct diagnosis essential.\(^7\)–\(^13\)

The diagnostic approach to RCD includes assessment of dietary adherence to a GFD and revision of the initial coeliac disease diagnosis. Re-evaluation of duodenal histopathology is mandatory, with immunohistochemical characterization aimed at identifying aberrant intraepithelial lymphocytes (IELs) and TCR\(\gamma\) chain clonality (regarded as pre- or low-grade lymphoma). Videocapsule endoscopy (VCE) is necessary to determine the extent of the lesions, whereas double balloon enteroscopy (DBE) can be useful for obtaining biopsy samples from distal lesions previously identified by imaging (i.e. entero-MR and entero-CT).\(^8\)–\(^14\) A practical algorithm summarizing the diagnostic process for RCD type 1 and 2 is shown in figure 1.

In this article, we discuss the mistakes most frequently made in patients who have suspected RCD, based on the available evidence and our clinical experience in the field.

Mistake 1 Misdiagnosing coeliac disease that is slow to respond as RCD

Once a diagnosis of coeliac disease has been established, clinical and mucosal healing is usually reached within 12 months as a result of gluten withdrawal (i.e. adoption of a GFD). However, some coeliac patients respond slowly to a strict GFD and continue to experience symptoms and incomplete recovery after 12 months. In these slow responders, full recovery may occur after 18–24 months.\(^15\) The appropriate approach in this situation is a...

Mistake 2 Diagnosing RCD if there is poor compliance to a GFD
Patients with coeliac disease feel the burden of long-term dietary restriction of gluten. Indeed, data indicate that only 60% of coeliac disease patients adhere strictly to a GFD. The remaining 40% of patients inadvertently, or (more commonly) willingly, reintroduce a significant amount of gluten into their diet, which causes the persistence of villous atrophy and gastrointestinal/extraintestinal symptoms. The lack of adherence to a GFD is reflected by high titres of anti-transglutaminase (TG2) antibodies, which continue to be detected in the serum of these patients. By contrast, RCD patients have either a negative or minimal increase (in approximately 10% of cases) in anti-TG2 antibodies. Physicians should advise all patients with coeliac disease about the risks of voluntarily introducing gluten, in terms of complications (such as RCD, enteropathy-associated-T-cell lymphoma [EATL], small bowel adenocarcinoma and ulcerative jejunoileitis), whereas resuming a strict GFD normalizes clinical and morphological (duodenal histology) features, preventing the possible occurrence of the above-mentioned complications.

Mistake 3 Diagnosing non-gluten-dependent intestinal villous atrophy as RCD
Patients who have a non-gluten-dependent villous atrophy can sometimes be mistakenly diagnosed as having seronegative coeliac disease. A thorough diagnostic work-up should be undertaken as it may identify conditions other than coeliac disease that are responsible for villous atrophy. Alternative causes include infections (e.g. with Giardia lamblia (giardiasis) or HIV), autoimmune enteropathy (characterized by anti-enterocyte autoantibodies), drug-induced enteropathy (e.g. caused by angiotensin II-receptor blockers [e.g. olmesartan], mycophenolate mofetil and NSAIDs), common variable immunodeficiency, small intestinal bacterial overgrowth (SIBO), Crohn’s disease, Whipple disease and eosinophilic gastroenteritis, among others. A simplified algorithm for the differential diagnosis of seronegative villous atrophy is shown in figure 2. Prior to labelling a patient as having RCD, it is mandatory to verify whether the initial diagnosis of coeliac disease was appropriate.

Mistake 4 Making a diagnosis of RCD based on incorrectly oriented biopsy samples
Biopsy samples should be adequately oriented in the endoscopy room in order to avoid obtaining false-positive results (i.e. a wrong interpretation of villous atrophy supporting the lack of response to a GFD). This is a critical issue that can be avoided by correct longitudinal orientation (along the length of the villi) of the biopsy samples using appropriate devices (i.e. a cellulose acetate filter). Endoscopists should take at least n=4 biopsy samples from the second part of the duodenum and n=2 from the duodenal bulb (the latter at the 9 o’clock and 12 o’clock position to maximize the histopathological yield). Histopathological reports, indicating persistence of villous atrophy, should be the result of adequately embedded and sectioned biopsy material according to the orientation given in the endoscopy room.

Mistake 5 Failing to recognise non-responsive coeliac disease
Physicians should be alert to avoiding the incorrect diagnosis of non-responsive coeliac disease as RCD. Patients who have

Figure 1 | Diagnosis of refractory coeliac disease. A practical algorithm that we developed to summarize the diagnostic process for refractory coeliac disease (RCD) type 1 and 2 compared with slow responding coeliac disease, nonresponsive coeliac disease and other nongluten-dependent enteropathies. EGDS, esophagogastroduodenal endoscopy; GFD, gluten-free diet; TCRγ, T-cell receptor γ.

Clinical improvement 12-18 months after coeliac disease diagnosis?

- NO
  - Positive serology after 12-18 months
  - Insufficient compliance with GFD
  - EGD with biopsy samples taken
  - No villous atrophy (March 0, 1, 2)
  - Grade 3b, 3c
  - Monoclonal lymphocytosis and TCR rearrangement

- YES
  - Negative serology after 12-18 months
  - Persistent villous atrophy
  - No villous atrophy (Marsh 0, 1, 2)
  - Grade 3a
  - Polyclonal lymphocytosis

RCD type 2
- RCD type 1
- No RCD

Continue follow-up

Persistent villous atrophy
- Exclude other causes of nonresponsive coeliac disease
- Check strict compliance with GFD
- Wait for slow responders
- Exclude other causes
- If no clinical response take repeat biopsy samples after 6-12 months

No villous atrophy
- Grade 3a
- Monoclonal lymphocytosis and TCR rearrangement
- Exclude other causes of nonresponsive coeliac disease
- Check strict compliance with GFD
- Wait for slow responders
- Exclude other causes
- If no clinical response take repeat biopsy samples after 6-12 months

EGD with biopsy samples taken
- No villous atrophy (March 0, 1, 2)
- Grade 3b, 3c
- Monoclonal lymphocytosis and TCR rearrangement
- Exclude other causes of nonresponsive coeliac disease
- Check strict compliance with GFD
- Wait for slow responders
- Exclude other causes
- If no clinical response take repeat biopsy samples after 6-12 months

Villous atrophy
- Grade 3a
- Polyclonal lymphocytosis
- Exclude other causes of nonresponsive coeliac disease
- Check strict compliance with GFD
- Wait for slow responders
- Exclude other causes
- If no clinical response take repeat biopsy samples after 6-12 months

Insufficient compliance with GFD
- Nonresponsive coeliac disease
- EGD with biopsy samples taken
- No villous atrophy (March 0, 1, 2)
- Grade 3b, 3c
- Monoclonal lymphocytosis and TCR rearrangement
- Exclude other causes of nonresponsive coeliac disease
- Check strict compliance with GFD
- Wait for slow responders
- Exclude other causes
- If no clinical response take repeat biopsy samples after 6-12 months

Negative serology after 12-18 months
- Nonresponsive coeliac disease
- EGD with biopsy samples taken
- No villous atrophy (March 0, 1, 2)
- Grade 3b, 3c
- Monoclonal lymphocytosis and TCR rearrangement
- Exclude other causes of nonresponsive coeliac disease
- Check strict compliance with GFD
- Wait for slow responders
- Exclude other causes
- If no clinical response take repeat biopsy samples after 6-12 months

EGDS, the diagnostic process for refractory coeliac disease (RCD) type 1 and 2 compared with slow responding
nonresponsive coeliac disease may complain of a wide array of symptoms, including bowel habit abnormalities, abdominal pain, bloating as well as nausea, vomiting and gastro-oesophageal reflux disease (GORD) symptoms. All such symptoms and/or signs are ascribable to other diseases that frequently overlap with coeliac disease (table 2). The differential diagnosis of nonresponsive coeliac disease versus RCD is based on thorough histopathological evaluation of duodenal biopsy samples, with normal villi cytoarchitecture visible in patients with nonresponsive coeliac disease compared with marked changes in patients with RCD.6

**Mistake 6 Diagnosing RCD when the intestinal mucosa has partially improved with a GFD**

A GFD can lead to clinical improvement in a proportion of coeliac disease patients who still have a mild villous atrophy at histopathology (lesion 3a according to the Marsh–Oberhüber classification).10 In these cases, the improvement of intestinal damage from grade 3b/3c (at diagnosis) to grade 3a (at follow-up) should be considered an indication of a positive outcome. Although there are no long-term studies, it is likely that this subset of patients will have complete intestinal villous regrowth over time.10

Table 2 | Diseases overlapping with coeliac disease that cause partial or no response to a gluten-free diet.

**Mistake 8 Delayed reassessment of mucosal histopathology in coeliac disease patients who experience late clinical worsening**

RCD can be classified clinically as primary and secondary subtypes. Primary RCD encompasses those patients who have no clinical/histopathological improvement from the time a GFD is begun; secondary RCD includes patients who experience sudden clinical worsening after many years of a very good response to a GFD.1,11 The mechanisms underlying these two phenotypes of RCD are largely unknown. Primary RCD patients are easily recognizable because of the absence of any clinical response to a GFD. By contrast, physicians should be aware that having a good clinical and histological response to a GFD for many years does not rule out the possible occurrence of secondary RCD. These cases should be reassessed by taking duodenal biopsy samples as early as possible to confirm the late refractoriness to a GFD.

**Mistake 9 Failing to make the distinction between RCD type 1 and type 2**

The distinction between RCD type 1 and type 2 is of paramount importance in clinical practice. This is mainly due to the evidence that RCD type 1 responds well to steroids and/or immunosuppressive treatments and has very good outcomes (5-year survival ranging from 80% to 96%), with a low risk of it evolving to EATL and ulcerative jejunoileitis. By contrast, RCD type 2 is not commonly responsive to various treatment options and has poor outcomes (5-year survival ranging from 44% to 58%), with a high risk of progression to complications such as EATL and ulcerative jejunoileitis.11
Mistakes in…

RCD type 2 differs from type 1 by having a high percentage of aberrant IELs (lacking surface CD3 and CD8, but expressing intracellular CD3 [iCD3]) detected by flow cytometry (table 1). Current criteria indicate that RCD type 1 is histopathologically characterized by <20% of aberrant IELs, whereas RCD type 2 is characterized by >20% of aberrant IELs (in some cases up to 90%).

Moreover, RCD type 2 is characterized by a mononuclear rearrangement of TCRγ chain that can be detected by immunohistochemistry.

Mistake 10 Inappropriate diagnostic work-up for EATL in patients with RCD type 2

A critical aspect of the possible evolution of patients with RCD type 2 to EATL is that it occurs more commonly in patients of advanced age and if there has been late diagnosis of coeliac disease. In this context, increased levels of lactate dehydrogenase and β2-microglobulin suggest that RCD has evolved to EATL. Imaging tests are of paramount importance in order to allow for early recognition of EATL, which is a life-threatening complication of RCD type 2. Once the diagnosis of EATL is suspected, physicians should recommend positron emission tomography (PET), which is the best exam to identify lymphoproliferative foci throughout the small intestine and their possible extension to the bone marrow. Enteroscopy (with ERCP) or enteroclysis is needed to identify small intestinal lesions and, therefore, guide endoscopic assessment via DBE, which is useful for obtaining biopsy samples for accurate histopathological analysis. Compared with DBE, VCE appears to have a low diagnostic yield (it does not enable the taking of biopsy samples) and could be harmful for patients with EATL or ulcerative jejunoileitis because of the possible risk of device retention.
